

Anomalous Properties of Weak-Links-Containing Superconductors: Flicker Noise

Sergei A. Sergeenkov

Low-frequency magnetic noise spectral density is calculated within the superconductive glass model. The model predicts the existence of both white noise and flicker-like noise $f^{-\alpha}$ with α strongly dependent on applied magnetic field and temperature. It is shown, in particular, that α increases with field from 0.5 to 1, and that in the critical region (near $T_c(H)$) the $1/\sqrt{f}$ law should prevail in the noise spectrum.

I. INTRODUCTION

Probably the most intriguing, perplexing, and still unresolved problem in SQUIDology is the problem of noises (see, e.g.,¹ and references therein). As was indicated by Donaldson², all high- T_c RF SQUIDS suffer from excessive $1/f$ noise contributions at low frequencies generated by a dense network of superconducting loops ($\simeq 10\mu m$ in diameter) interrupted by Josephson junctions. According to Gross et al.³, the temperature and field dependencies of the flux noise power spectrum in DC SQUIDS strongly correlate with the similar behavior of the critical current (magnetization) in weak-link-containing systems. Gabovich et al.⁴ observed the flicker noise in ceramic superconductor $BaPb_{0.75}Bi_{0.25}O_3$ in the range $20Hz \leq f \leq 500Hz$ with the noise spectral density $S_m(f)$ well-fitted by the law $f^{-\alpha}$, where α increases with applied field.

On the other hand, as was shown in our previous paper⁵, the superconductive glass (SG) model enables us to describe quite satisfactory experimentally observed anomalies of critical currents and current-voltage characteristics of weak-link-containing superconductors (such as ceramics and defected single crystals).

In this paper we consider via the SG model the low-frequency noise properties of granular superconductors due to the long-time magnetization fluctuations of the sample.

II. THE SG MODEL

As is well known^{5,6} the Hamiltonian of the SG model in the pseudospin representation has a form

$$\mathcal{H} = -Re \sum J_{ij} S_i^* S_j, \quad (1)$$

where

$$J_{ij} = J(T) e^{iA_{ij}}, \quad S_i = e^{i\phi_i}, \quad (2)$$

with

$$A_{ij} = \pi H(x_i + x_j)(y_i - y_j)/\Phi_0. \quad (3)$$

The model (1) describes the interaction between superconductive clusters (with phases ϕ_i) via Josephson junctions (with an energy $J(T)$) on 2D disordered lattice (with cluster coordinates (x_i, y_j)) in a frustrated external magnetic field $\mathbf{H} = (0, 0, H)$. The field is normal to the ab -plane where a glass-like picture of high- T_c oxides is established^{5,6}.

According to the fluctuation-dissipation theorem we calculate the enhancement of excess magnetic noise density within the SG model:

$$S_m(f) = \int_0^\infty dt \cos(2\pi ft) \langle M(t)M(0) \rangle \quad (4)$$

where

$$\begin{aligned} M(t) &= M(H)D(t), \\ M(H) &= -M_0(H/H_0)(1 + H^2/H_0^2)^{-3/2}, \end{aligned} \quad (5)$$

and

$$H_0 = \Phi_0/2S, \quad M_0 = \text{SNJ}/\Phi_0. \quad (6)$$

Here $S^{1/2}$ is an average grain size. The correlator $D(t) = D_{ii}(t)$ determines all the dynamical properties of the model and is defined as follows:

$$D_{ij}(t) = \langle S_i(t)S_j^*(0) \rangle \quad (7)$$

The bar denotes the Gauss-like averaging over random grain coordinates (x_i, y_j) with a mean square deviation S/π . In the mode-coupling approximation one obtains the self-consistent equation in correlator $D(t)$:

$$d^2 D/dt^2 + \Omega^2 D(t) + \int_0^t dt' K(t-t')[dD(t')/dt'] = 0 \quad (8)$$

The Laplace transform of the memory kernel $K(t)$ in the pair spin approximation has the form⁵:

$$\begin{aligned} K_{ij}(z) &= \Omega^2 F(T, H_0)[D_{ij}(z) \\ &+ i \int_0^\infty dt e^{izt} \sum_{kl} D_{ik}(t)D_{kl}(t)D_{lj}(t)] \end{aligned} \quad (9)$$

where

$$F(T, H) = J^2(T, H)/T^2, \quad (10)$$

$$J(T, H) = J(T)/(1 + H^2/H_o^2)^{1/2}.$$

Here $\Omega = 2e^2 RT/h^2 N$ is a characteristic frequency of the system (1), N is the number of superconducting grains (or weak links).

Let us consider the solution of system (6)-(7) for equilibrium relaxation in the form:

$$D(t) = L + (1 - L)\Phi(t). \quad (11)$$

Here we have introduced the nonergodicity (order) parameter $L(T, H)$ which is defined via correlator $D(t)$ as^{5,6}:

$$L(T, H) = \lim_{t \rightarrow \infty} D(t) \quad (12)$$

From⁵ it is known that the transition temperature $T_c(H)$ to the *SG* state is determined by the equation $L(T_c, H) = 0$. Taking into account eq.(9) from eqs.(6) and (7) we obtain the equation for L :

$$L^3 - L^2 + L - (1 - T^2/T_c^2(H)) = 0. \quad (13)$$

Using as Ansatz a power-like relaxation law:

$$\Phi(t) = (1 + t/\tau)^{-n}, \quad (14)$$

for the exponent $n(T, H)$ one obtains near $T_c(H)$:

$$n = 1/2 + L/(1 - L) \quad (15)$$

III. FLICKER NOISE IN THE SG MODEL

To obtain the magnetic noise density due to the magnetization fluctuations within the *SG* model we use the power-law Ansatz (11). Taking into account eqs. (4), (8), (11), and (12) from eq.(3) one gets finally:

$$S_m(f) = S_o(H)[L\delta(f) + (1 - L)\tau\Gamma(\alpha)(f\tau)^{-\alpha}], \quad (16)$$

where

$$\alpha(T, H) = 1 - n(T, H), \quad S_o(H) = M^2(H). \quad (17)$$

Thus, according to eq.(13), the magnetic fluctuations due to redistribution of the magnetic flux between Josephson network loops lead to emergence of the white noise with amplitude $S_o(H)L(T, H)$ and the flicker noise $f^{-\alpha}$ with amplitude $S_o(H)(1 - L)$. Near $T_c(H)$, as it follows from eq.(10), the order parameter $L \simeq 1 - [T/T_c(H)]^2$. In turn, the phase boundary $T_c(H)$ is determined by the equation $F(T_c, H) = 1$ (see eq.(7)), so that near $T_c(H)$ the white noise contribution is strongly depressed in comparison with the flicker noise one. Moreover, in view of eqs.(12) and (14), the power exponent α will increase with field H from $\alpha = 0.5$ (at low fields $H/H_o \ll 1$) to $\alpha = 1$ (at higher fields $H/H_o \geq 1$, when the *SG* state is established throughout the sample). It is important to stress that $\alpha(T_c, H) = 0.5$, i.e. in the critical region $1/\omega$ noise should prevail in the fluctuation spectrum.
